ANALYSIS OF CENTRAL WORTHS AND OTHER INTEGRAL DATA
FROM THE LOS ALAMOS BENCHMARK ASSEMBLIES

by

D. W. Muir

ABSTRACT

We have compared theoretical calculations, based on ENDF/B-V and recent revisions, with integral data measured on the Los Alamos unmoderated critical assemblies Godiva, Jezebel, Flattop-25, and Flattop-Pu. The experimental data included in this analysis are multiplication factors k_{eff} and (in most cases) both fission rates and central-worth ratios for ^{235}U , ^{238}U , ^{237}Np , and ^{239}Pu . Based on this comparison, we conclude that there is a need for a new ^{235}U evaluation, and increased accuracy is needed in certain integral measurements.

I. INTRODUCTION

Because of the availability of recently revised nuclear-data evaluations, as well as recent additions and corrections to the body of integral data, it is of interest to re-examine the experimental data for the Los Alamos unmoderated critical assemblies Godiva, Jezebel, Flattop-25, and Flattop-Pu and to compare these data with state-of-the-art theoretical predictions. The experimental data included in our analysis are multiplication factors k_{eff} and (in most cases) fission rates and worth ratios for ^{235}U , ^{238}U , ^{237}Np , and ^{239}Pu . Preliminary numerical values of these measured quantities are given in Ref. 1.

II. CALCULATIONAL METHOD

As a test of the standard approach (first-order perturbation theory) to the calculation of central worths, we have used the ONEDANT neutron transport code,² together with TRANSX multigroup cross-section post-processing program,³ to calculate all worths using the "direct" method. That is, we calculated k_{eff} for a reference assembly with a very tight convergence criterion ($\text{EPSO} = 10^{-7}$)

and then recalculated it with the same criterion for a series of "perturbed" configurations. In all ONEDANT calculations, an S_{16} angular quadrature was employed.

The atomic compositions and radial dimensions of the one-dimensional models used in this study are given in Table I, which is adapted from Ref. 4. The geometrical meshes used in our ONEDANT runs were slightly different from those used in Ref. 4, which recommended a uniform mesh with 40 total intervals in both Godiva and Jezebel and a 30/30 (core/reflector) mesh in the Flattops. The main difference is that in all of our calculations there was an "inner core" region, 0.5 cm in radius, finely zoned into 20 intervals. In Godiva and Jezebel, the remainder of the assembly contained 40 equally spaced intervals. In the Flattops, two zoning strategies were employed outside the inner core. To save time, a relatively coarse mesh, consisting of 20 equally spaced intervals in the outer core and 20 in the reflector, was used in the lengthy perturbation series of calculations. A finer 20/40/40 zoning was then used in a separate k_{eff} "benchmark" calculation.

TABLE I
BENCHMARK SPECIFICATIONS

Material	Godiva	Flattop-25		Jezebel	Flattop-Pu	
		Core	Refl.		Core	Refl.
Ga				0.001375	0.00138	
U-234	0.000492	0.00049				
U-235	0.04500	0.04449	0.00034			0.00034
U-238	0.002498	0.00270	0.04774			0.04774
Pu-239				0.03705	0.03674	
Pu-240				0.001751	0.00186	
Pu-241				0.000117	0.00012	
Radius (cm)	8.741	6.116	24.13	6.385	4.533	24.13

In the perturbation series, the atomic density ρ of a selected "perturbed nuclide" (not necessarily present in the reference assembly) was gradually increased from its reference value within the 0.5-cm radius inner core until a net change in k_{eff} of a few parts in 10^4 was obtained. For ^{235}U and ^{237}Np , the set of density increments $\Delta\rho$ actually employed is (0., 0.001, 0.002, 0.005, 0.01, and 0.02), all expressed in units of atoms/barn-cm. For ^{238}U , the set

used is (0., 0.005, 0.01, 0.02, 0.05, and 0.1) and for ^{239}Pu (0., 0.0005, 0.001, 0.002, 0.005, and 0.01). The perturbed nuclide was added "interstitially," that is, without simultaneously removing other materials from the reference assembly. This procedure should provide a reliable estimate of the initial slope

$$\left. \frac{dk}{d\rho} \right|_{\rho = 0} ,$$

which is identical, except for a multiplicative factor, to the "reactivity coefficient" normally quoted. In addition, our results may provide a useful calculational benchmark for testing various perturbation-theory methods for predicting the value of the second derivative

$$\left. \frac{d^2k}{d\rho^2} \right|_{\rho = 0} .$$

III. NUCLEAR DATA

The cross sections used for neutron transport in the materials of a given reference assembly were either (a) original ENDF/B-V for all materials or (b) ENDF/B-V for all materials but ^{239}Pu , and Revision 2 of ENDF/B-V for that nuclide. The cross sections for four of the perturbed nuclides were taken from original ENDF/B-V: ^{235}U (25), ^{238}U (28), ^{237}Np (37), and ^{239}Pu (49). In addition, and treated as data for distinct perturbed nuclides, were a recent T-2 reevaluation⁵ for ^{237}Np (37A) and the new Revision 2 evaluation⁶ for ^{239}Pu (49A). Thus, there were six reference "assemblies," namely, Godiva, Flattop-25, Jezebel(V), Flattop-Pu(V), Jezebel(V.2), and Flattop-Pu(V.2), and six perturbed "nuclides," namely, 25, 28, 37, 37A, 49, and 49A.

Cross-section sets for all materials contained in Godiva, Jezebel, and the two Flattops (see Table I), plus ^{237}Np , were already available⁵ in the Los Alamos 80-group neutron structure. The GENDF files discussed in Ref. 5 were retrieved and merged into a single GENDF. This was, in turn, converted to MATXS format using the NMATXS module of NJOY (Ref. 7). The resulting MATXS-formatted library, called MATXS80, is available on request. MATXS80 was read repeatedly with the TRANSX³ program, in order to generate perturbed cross-section sets in the XSLIB format, one of the cross-section input formats read by ONEDANT. P_3 transport-corrected tables were produced using the Bell-Hansen-Sandmeier formulation.

IV. RESULTS

For each of the six reference assemblies, we performed one unperturbed ONEDANT k-calculation and 30 perturbed k-calculations (6 nuclides \times 5 nonzero densities).

The six k_{eff} values obtained for a given assembly/nuclide combination were then fit with a second-order polynomial,

$$k_{\text{eff}}(\rho) \cong A + B\rho + C\rho^2, \quad (1)$$

using an unweighted least-squares algorithm. The results of recalculating k_{eff} values with these A, B, and C values, when rounded to the eight digits supplied on the ONEDANT output listing, were in perfect agreement with the ONEDANT values. Thus, no evidence was found for irregularities in the ρ -dependence, and furthermore, no evidence was found for the presence of a ρ^3 contribution. The maximum deviation from linearity, that is,

$$\left. \frac{C\rho^2}{B\rho} \right|_{\rho = \rho_{\text{max}}}$$

was around 10% for ^{238}U and less than 2% for all other perturbed nuclides. A complete list of the A, B, and C values obtained for the six reference assemblies and the six perturbed nuclides is given in Table II.

From the form of Eq. (1), it is clear that $\left. \frac{dk}{d\rho} \right|_{\rho = 0} = B$.

Thus, the values of B in Table II can easily be converted to absolute reactivity coefficients, in units of \$/kg or \$/mole. However, for the purposes of data testing, the main information is contained in worth ratios such as

$$\frac{\Delta k(28)}{\Delta k(25)} \equiv \frac{\left. \frac{\partial k}{\partial \rho_{28}} \right|_{\rho_{28} = 0}}{\left. \frac{\partial k}{\partial \rho_{25}} \right|_{\rho_{25} = 0}} = \frac{B(28)}{B(25)}$$

For a variety of reasons, these ratios can be measured and calculated much more accurately than the corresponding absolute values.

^a "Data" here refers to the bulk-transport cross sections, which were held constant during a series of perturbation calculations.

As a final step in the calculation of worth ratios, in the case of the new neptunium evaluation⁵ it was necessary to estimate the relative worth of delayed neutrons from fission of ^{237}Np , because the GENDF multigroup fission matrices did not contain delayed neutrons in this case. This effect is estimated to increase $\Delta k(37A)/\Delta k(25)$ by a factor of 1.01 with an uncertainty of about 0.5%, which is smaller than the uncertainty of the corresponding measurements.

In Table III, results are presented for the calculated and measured (Ref. 1) worth ratios and fission ratios for the two ^{235}U -fueled assemblies, Godiva and Flattop-25. In all cases where an ENDF/B-V "nuclide" is placed in an ENDF/B-V "assembly," it is possible to compare our results, obtained using the direct method, with the results (shown in parentheses) obtained in Ref. 4 using first-order perturbation theory (and using a slightly different group structure, plus other minor calculational differences). The agreement is excellent, and this adds confidence in both the results of the current study and those reported in Ref. 4.

Since Flattop-25 has a ^{238}U reflector, the central neutron flux is somewhat softer than in Godiva. This is manifested in Table III by the lower worth and fission ratios for the threshold fissioners (^{238}U and ^{237}Np) in Flattop-25. Another obvious feature of these results is that the C/E values for the worth and fission ratios are systematically high in both assemblies for these same nuclides. It is clear that modification of the ^{235}U transport cross sections in some fashion, so as to soften the central flux, would improve the agreement of the calculated results with the measurements. Another clear result is that the new neptunium evaluation performs considerably better here than does the ENDF/B-V evaluation. It is not possible, at this point, to say whether the remaining neptunium discrepancies (for example, the C/E value of 1.09 ± 0.01 for $\Delta k(37A)/\Delta k(25)$ in Flattop-25) are due entirely to the ^{235}U spectrum effect or whether they are partially caused by remaining problems in ^{237}Np . This question can only be answered when an improved evaluation for ^{235}U becomes available.

In Table IV are given the results for the two ^{239}Pu -fueled assemblies, where the reference cross sections for ^{239}Pu are the original ENDF/B-V data. Here there is evidence in the fission ratios for ^{238}U and ^{237}Np that the calculated central spectrum is too soft. This trend was part of the motivation for a recent re-examination of the ^{239}Pu data situation. The result of this work⁶ is the ^{239}Pu evaluation issued in Revision 2 of ENDF/B-V.

Adopting the Revision 2 evaluation as the reference, one obtains the results given in Table V. There is noticeable improvement here in the fission ratios for ^{238}U and ^{237}Np . The "benchmark" (fine-mesh) calculations of k_{eff} are also now in better agreement with the measurements.

However, the situation with the ^{238}U and ^{237}Np worths is not as good. In these calculations, using the latest ^{239}Pu evaluation to calculate the central neutron spectrum and the latest cross sections for the threshold fissioners, we still have a C/E of 1.16 ± 0.04 for the $^{238}\text{U}/^{235}\text{U}$ worth ratio in Flattop-Pu (V.2) and a C/E of 1.08 ± 0.06 for $^{237}\text{Np}/^{235}\text{U}$ in Jezebel(V.2). It is interesting that the more discrepant C/E occurs in the relatively soft Flattop-Pu spectrum for ^{238}U and in the harder Jezebel spectrum for ^{237}Np . From this, it is clear that "fine tuning" of the ^{239}Pu spectrum cannot solve both problems simultaneously. Although it is risky to try to explain discrepancies in complex systems in terms of just a few cross sections, one could speculate that there are problems in the ^{238}U cross sections at low energies and/or some slight problems in ^{237}Np at higher energies. Any stronger conclusion than this must await the availability of worth-ratio measurements with higher accuracy.

It is also of interest to note the slight, but systematic, discrepancies in the Jezebel fission ratios. It is difficult to think of a single change that would improve all three ratios, other than a 3% lowering of the ^{235}U fission cross section in a Jezebel-type spectrum. This large a change would be at the outer limits of the uncertainty specified by the ENDF/B-V evaluators. Because of the close connection between σ_f and worth, such a change would aggravate the worth-ratio discrepancies just discussed.

An overall trend worth mentioning is that the addition of the ^{238}U reflector (for example, Godiva \rightarrow Flattop-25) has the effect, in each case, of raising the k_{eff} C/E ratio and in all cases this is a change for the worse. This trend reinforces the earlier suggestion of problems in the ^{238}U cross sections at the lower energies.

Another point of interest is that the rising ^{238}U worth-ratio C/E values in the series [Godiva, Flattop-25, Jezebel(V.2), Flattop-Pu(V.2)] are strongly correlated with rising ^{238}U (absolute) worths in these assemblies (see Table II). Although many explanations could be offered for this correlation, at least one possibility worth examining is difficulties in the experimental data reduction such as the treatment of nonlinear effects, which are especially important for ^{238}U .

V. CONCLUSIONS

By the use of a straightforward direct method, we have validated the worth ratios previously calculated⁴ using first-order perturbation theory. In the area of nuclear data, we see evidence for the need to revise the ^{235}U cross sections, both to soften the central neutron spectrum in ^{235}U -fueled assemblies and to reduce the average ^{235}U fission cross section in ^{239}Pu -fueled assemblies. We find that the new ^{239}Pu evaluation⁶ improves the C/E values in most respects, although the high C/E values for the worth ratios of threshold fissioners are not understood. We find that the new ^{237}Np evaluation⁵ offers improvements in most areas over the ENDF/B-V evaluation and that ^{237}Np C/E ratios are generally superior to the corresponding ^{238}U values. Detailed recommendations for further improvements in the data for the threshold fissioners must await improvements in the ^{235}U evaluation and in the accuracy of some of the integral measurements.
